Title of the Invention

Amplitude Limiting Circuit and
CDMA Communication Apparatus

5

Background of the Invention

The present invention relates to an amplitude limiting circuit and, more particularly, to an amplitude limiting circuit which can be suitably used to limit an 10 input to a transmission power amplifier incorporated in a CDMA communication apparatus.

Recent digital mobile communication systems often use CDMA (Code Division Multiple Access) communication apparatuses to improve the interference 15 resistance ability between communication channels.

In a CDMA communication apparatus, since the instantaneous power at the time of transmission is much higher than the average power, the linearity of a transmission power amplifier must be maintained up to a 20 very high output level to suppress spreading of a transmission spectrum due to nonlinear distortion so as to reduce adjacent channel leakage power.

A power amplifier designed to have good linearity up to a very high amplitude has a large 25 circuit size, and hence increases in cost and power consumption. For this reason, as a transmission power amplifier for a CDMA communication apparatus, a

nonlinear compensation amplifier is used, which exhibits good linearity with respect to small amplitude components and nonlinearity with respect to large amplitude components. As shown in Fig. 5, the linearity 5 of this nonlinear compensation amplifier has the input/output characteristics that linearity is maintained up to its maximum output, and when an input amplitude exceeds a value corresponding to the maximum output, the output level becomes constant.

10 In a transmission power amplifier having input/output characteristics like those shown in Fig. 5, when a signal corresponding to a level exceeding the maximum output is input, a transmission output is saturated to increase nonlinear distortion. As a 15 consequence, the transmission spectrum spreads to increase adjacent channel leakage power, as indicated by the spectrum waveform without "CLIPPING" in Fig. 6.

It is therefore desirable to maximize the saturation power (maximum output) of the transmission 20 power amplifier. In this case, however, as described above, the circuit size increases to increase power consumption and cost. For this reason, it is important in the CDMA communication apparatus that the instantaneous maximum power of an input signal is 25 limited so as not to exceed the saturation power of the transmission power amplifier.

The simplest method of limiting the input

amplitude of the transmission power amplifier is to clip an input signal with a predetermined value. If, however, an input signal is simply clipped, the nonlinear distortion of a signal waveform increases. As a result, 5 the transmission spectrum further spreads, as indicated by the spectrum waveform obtained by "SIMPLE CLIPPING" in Fig. 6. As shown in Fig. 7, therefore, an amplitude limiting circuit is generally provided before a band limiting filter.

10 An amplitude limiting circuit 20 shown in Fig. 7 includes an amplitude converter 21 which calculates the amplitude value of an input signal constituted by an in-phase component I and quadrature component Q, a determination unit 22 which compares the 15 amplitude value calculated by the amplitude converter 21 with a preset threshold to output a control value for limiting the amplitude of an input signal that exceeds the threshold, and a clipping circuit 23 which limits an output amplitude to a value equal to or less than the 20 threshold in accordance with the control value output from the determination unit 22.

Of an output signal from the amplitude limiting circuit 20, only a predetermined baseband component is output from a filter 24. In this 25 arrangement, since the frequency component of an output signal is limited by the filter 24 within a predetermined band, the transmission spectrum does not

spread.

In the arrangement shown in Fig. 7, however, since the amplitude limiting circuit and filter 24 differ in their sampling rates for signal processing, 5 level variations occur at the time of sampling. As a result, the amplitude of the signal passing through the filter 24 may increase again.

In addition, when the amplitude limiting circuit shown in Fig. 7 is applied to a CDMA 10 communication apparatus of a so-called multicarrier amplification scheme of combining a plurality of carrier signals, shown in Fig. 8, the amplitude of the signal is increased again by processing after amplitude limitation.

The CDMA communication apparatus shown in 15 Fig. 8 includes a plurality of amplitude limiting circuits 31₁ to 31_N (N is a positive integer) which limit the amplitudes of input signals and a plurality of filters 32₁ to 32_N which pass only predetermined band components.

20 The CDMA communication apparatus also includes first frequency converters 33₁ to 33_N which convert input signals as baseband signals into signals having different frequencies for the respective channels, and a carrier combining unit 34 which combines output signals 25 from the first frequency converters 33₁ to 33_N.

The CDMA communication apparatus further includes a D/A converter 35 which converts the signal

obtained by carrier combining into an analog signal, a second frequency converter 36 which converts the output signal from the D/A converter 35 into an RF signal, and a transmission power amplifier 37 which amplifies the RF 5 signal to power necessary for transmission.

The CDMA communication apparatus includes the amplitude limiting circuits 31₁ to 31_N, filters 32₁ to 32_N, and first frequency converters 33₁ to 33_N for the respective channels.

10 In this arrangement, since signals corresponding to a plurality of channels are subjected to vector combining in the carrier combining unit 34 after amplitude limitation, the effect of the amplitude limitation is lost. As a consequence, the transmission 15 spectrum spreads, as indicated by the spectrum waveform of "CONVENTIONAL SCHEME" in Fig. 9.

Summary of the Invention

The present invention has been made to solve the above problems in the prior art, and has as its 20 object to provide an amplitude limiting circuit which can be effectively used to limit an input to a transmission power amplifier incorporated in a CDMA communication apparatus.

In order to achieve the above object, 25 according to the present invention, there is provided an amplitude limiting circuit for limiting an amplitude of a signal input to a power amplifier, comprising an

amplitude converter which calculates an amplitude value of an input signal, a determination unit which detects, as a detection interval, an interval in which the amplitude value exceeds a threshold, on the basis of a 5 preset threshold and the amplitude value of the input signal, a peak detector which detects, in the detection interval, a peak time when a maximum amplitude value appears and an amplitude value at the peak time as a peak value, a window filter which generates a window 10 function for limiting the amplitude value to a value not more than the threshold by using the peak value output from the peak detector, a delay circuit which delays the input signal such that the peak time output from the peak detector coincides with time when the window 15 function output from the window filter exhibits a minimum value, and a multiplier which multiplies an output signal from the delay circuit by the window function.

Description of the Preferred Embodiment

The present invention will be described next with reference to the accompanying drawings.

25 As shown in Fig. 1, an amplitude limiting circuit according to the present invention includes an amplitude converter 1 which calculates the amplitude

value of an input signal constituted by an in-phase component I and quadrature component Q and a determination unit 2 which is connected to the amplitude converter 1 and compares a preset threshold with an 5 output value from the amplitude converter to detect an interval in which the amplitude value of the input signal exceeds the threshold.

The amplitude limiting circuit also includes a peak detector 3 which is connected to the determination 10 unit 2 and detects, in the interval in which the amplitude value of the input signal exceeds the threshold, the time (peak time) when the maximum amplitude value appears and the maximum value (peak value), and a window filter 4 which is connected to the 15 peak detector 3 and generates a predetermined window function by using the values detected by the peak detector 3.

In addition, the amplitude limiting circuit includes a delay circuit 5 which delays the input signal 20 by a predetermined delay amount and a multiplier 6 which is connected to the delay circuit 5 and multiplies an output signal from the delay circuit 5 by the window function generated by the window filter 4.

As shown in Fig. 1, the input signal to the 25 amplitude limiting circuit is a signal which is constituted by the in-phase component I and quadrature component Q and has undergone filtering processing and

carrier combining.

The amplitude converter 1 calculates an amplitude value P of the input signal from the in-phase component I and quadrature component Q by

$$5 \quad \mathbf{P} = (\mathbf{I}^2 + \mathbf{Q}^2)^{1/2} \quad \dots (1)$$

The determination unit 2 includes an amplitude value comparing section 2a which compares the amplitude value calculated by the amplitude converter 1 with a threshold to determine whether or nor the amplitude value exceeds the threshold, and interval detecting section 2b which detects an interval in which the amplitude value of the input signal exceeds the threshold.

Note that the threshold is set by a threshold input section 7 in advance to a value equal to or less than an input amplitude at which the output of a transmission power amplifier located after the amplitude limiting circuit is not saturated.

In the interval in which it is determined that
20 the amplitude value of the input signal exceeds the
threshold, the peak detector 3 outputs the peak time
when the maximum amplitude value appears and the peak
value at the peak time.

The window filter 4 outputs a window function which exhibits a value of 1 before and after a preset correction interval longer than the interval in which the amplitude value of the input signal exceeds the

threshold, and makes the value at the center of the correction interval proportional to the reciprocal of the peak value.

The delay circuit 5 delays the input signal 5 such that the peak time coincides with the center of the correction interval. The signal output from the delay circuit 5 is multiplied by the window function output from the window filter 4.

As shown in Fig. 2, a CDMA communication 10 apparatus of this embodiment includes a plurality of filters 11_1 to 11_N (N is a positive integer) which pass only predetermined band components, and a plurality of first frequency converters 12_1 to 12_N which are respectively connected to the filters 11_1 to 11_N and 15 convert baseband signals passing through the filters into signals with different frequencies for the respective channels.

The CDMA communication apparatus also includes a carrier combining unit 13 which is connected to the 20 first frequency converters 12_1 to 12_N and combines output signals from the first frequency converters 12_1 to 12_N , and an amplitude limiting circuit 14 which is connected to the carrier combining unit 13 and limits the amplitude of the signal obtained by carrier 25 combining.

In addition, the CDMA communication apparatus includes a D/A converter 15 which is connected to the

amplitude limiting circuit 14 and converts the amplitude-limited signal into an analog signal, a second frequency converter 16 which is connected to the D/A converter 15 and converts an output signal from the D/A converter 15 into an RF signal, and a transmission power amplifier 17 which is connected to the second frequency converter 16 and amplifies the RF signal to power necessary for transmission.

That is, the CDMA communication apparatus includes a filter 11 and first frequency converter 12 for each channel.

In this arrangement, since amplitude limitation is performed with respect to the signal obtained by filtering by the filters 11₁ to 11_N and carrier combining, there is no chance that the signal amplitude increases again by processing after amplitude limitation as in the prior art.

The operation of the amplitude limiting circuit according to the present invention will be described next with reference to Figs. 3 and 4.

In the amplitude limiting circuit of this embodiment, the amplitude converter 1 converts an input signal into an amplitude value, and the determination unit 2 compares the amplitude value with a preset threshold. If the amplitude value exceeds the threshold, the peak detector 3 detects the peak time when the maximum amplitude appears and the peak value at the time.

The window filter 4 generates a function exhibiting a value which is 1 until the peak value, gradually decreases thereafter to become A (= threshold/peak value) after a lapse of a time τ , and 5 gradually increases thereafter to return to 1 after a lapse of the time τ (see "WINDOW FUNCTION" in Fig. 3).

In this case, τ is set in advance to a value half a value corresponding to a time longer than the interval in which the input signal exceeds the threshold. 10 For example, a value about 10 to 20 times the chip period is used.

Note that the chip period is the reciprocal of the spreading frequency (= chip rate) used in the CDMA communication apparatus. Referring to Fig. 3, the unit 15 of time on the abscissa is represented by "CHIP", which indicates that a given time corresponds to a specific multiple of the chip rate.

The input signal is delayed by the time τ by the delay circuit 5 (see "DELAY CIRCUIT OUTPUT" in 20 Fig. 3). This signal is then multiplied by the window function generated by the window filter 4, and the resultant signal is output (see "OUTPUT SIGNAL" in Fig. 3). At this time, the multiplier 6 outputs a signal which is wave-shaped such that the peak value is 25 equal to or less than the threshold.

The window filter 4 generates, for example, a window function $w(t)$ represented by

$$w(t) = \begin{cases} 1 - a \left(1 - \cos \left(\frac{\pi t}{\tau} \right) \right) & (0 < t < 2\tau) \\ 1 & (t < 0, 2\tau < t) \end{cases}$$

In this case, when $t = \tau$, it suffices if $w(t) = 1 - 2a \leq A$. For example, $a = (1 - A)/2$ is set.

As shown in Fig. 2, in the CDMA communication apparatus of this embodiment, since amplitude limitation is performed with respect to the signal obtained by filtering by the filters and carrier combining, there is no chance that the signal amplitude increases again by processing after amplitude limitation as in the prior art.

Therefore, this apparatus is free from nonlinear distortion which is caused when a transmission output from the transmission power amplifier 17 on the output stage is saturated, and hence spreading of a transmission spectrum is suppressed. This makes it possible to suppress adjacent channel leakage power.

The amplitude limiting circuit of this embodiment smoothly limits the amplitude of an input signal by using a window function instead of simply clipping the input signal. This prevents the occurrence of nonlinear distortion due to amplitude limitation processing, and hence suppresses spreading of a transmission spectrum as indicated by the waveform based on "SCHEME ACCORDING PRESENT INVENTION".

The present invention is configured in the

above manner, and hence has the following effects.

An amplitude limiting circuit according to the present invention includes an amplitude converter which calculates the amplitude value of an input signal, and a 5 determination unit which compares a preset threshold with the amplitude value of the input signal to detect an interval in which the amplitude value exceeds the threshold.

The amplitude limiting circuit also includes a 10 peak detector which detects, in the interval in which the amplitude value of the input signal exceeds the threshold, the peak time when the amplitude value of the input signal becomes maximum and the amplitude value at the peak time, and a window filter which generates a 15 window function for limiting the amplitude value of the input signal to a value equal to or less than the threshold by using the peak value.

The amplitude limiting circuit further includes a delay circuit which delays the input signal 20 such that the peak time coincides with the time when the window function exhibits the minimum value, and a multiplier which multiplies an output signal from the delay circuit by the window function.

With this operation, the amplitude of the 25 input signal is limited to a value equal to or less than the threshold by using the window function, and hence no nonlinear distortion is caused by amplitude limitation

processing. This makes it possible to suppress spreading of the transmission spectrum.

A CDMA communication apparatus according to the present invention includes a plurality of filters 5 which pass predetermined band components containing input signals, and a plurality of first frequency converters which convert the signals passing through the filters into signals with different frequencies for the respective channels.

10 The CDMA communication apparatus also includes a carrier combining unit which combines output signals from the first frequency converters, the above amplitude limiting circuit which limits the amplitude of an output signal from the carrier combining unit, and a D/A 15 converter which converts an output signal from the amplitude limiting circuit into an analog signal.

The CDMA communication apparatus further includes a second frequency converter which converts the analog signal into an RF signal, and a transmission 20 power amplifier which amplifies the RF signal to power necessary for transmission.

With this operation, the amplitude of an output signal from the carrier combining unit is limited by the above amplitude limiting circuit to perform 25 amplitude limitation with respect to the signal obtained by filtering by the baseband filters and carrier combining. This prevents the signal amplitude from

increasing again due to processing after amplitude limitation as in the prior art.

Therefore, this apparatus is free from nonlinear distortion which is caused when a transmission 5 output from the transmission power amplifier on the transmitting side is saturated, and hence spreading of a transmission spectrum is suppressed. This makes it possible to suppress adjacent channel leakage power.
